Please Note

IBM's statements regarding its plans, directions, and intent are subject to change or withdrawal without notice at IBM's sole discretion. Information regarding potential future products is intended to outline our general product direction and it should not be relied on in making a purchasing decision.

The information mentioned regarding potential future products is not a commitment, promise, or legal obligation to deliver any material, code or functionality. Information about potential future products may not be incorporated into any contract. The development, release, and timing of any future features or functionality described for our products remains at our sole discretion.

Performance is based on measurements and projections using standard IBM benchmarks in a controlled environment. The actual throughput or performance that any user will experience will vary depending upon many factors, including considerations such as the amount of multiprogramming in the user's job stream, the I/O configuration, the storage configuration, and the workload processed. Therefore, no assurance can be given that an individual user will achieve results similar to those stated here.

Agenda

- What are the main performance costs inside message flows?

... and what are the best practices that will minimize these costs?

- What other performance considerations are there?
- Understanding your integration node's behavior

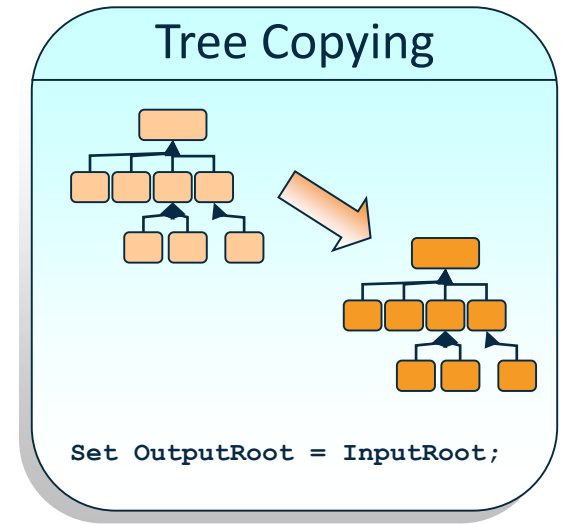

Why should you care about performance?

- Optimising performance can lead to real \$\$ savings... Time is Money!
 - Lower hardware requirements, lower MIPS
 - Maximised throughput... improved response time
 - Ensure your SLAs are met

- IBM Integration Bus is a sophisticated product
 - There are often several ways to do things... which is the best?
 - Understanding how Integration Bus works allows you to write more efficient message flows and debug problems more quickly
- It's better to design your message flows to be as efficient as possible from day one
 - Solving bad design later on costs much more
 - Working around bad design can make the problem worse!

What are the main performance costs inside message flows?

Complete your session evaluations online at www.SHARE.org/Orlando-Eval

When this or any other message flow processes messages costs arise.

These costs are:

- **Parsing.** This has two parts. The processing of incoming messages and the creation of output messages. Before an incoming message can be processed by the nodes or ESQL it must be transformed from the sequence of bytes, which is the input message, into a structured object, which is the message tree. Some parsing will take place immediately such as the parsing of the MQMD, some will take place, on demand, as fields in the message payload are referred to within the message flow. The amount of data which needs to be parsed is dependent on the organization of the message and the requirements of the message flow. Not all message flows may require access to all data in a message. When an output message is created the message tree needs to be converted into an actual message. This is a function of the parser. The process of creating the output message is referred to as serialization or flattening of the message tree. The creation of the output message is a simpler process than reading an incoming message. The whole message will be written at once when an output message is created. We will discuss the costs of parsing in more detail later in the presentation.
- **Message/Business Processing.** It is possible to code message manipulation or business processing in any one of a number of transformation technologies. These are ESQL, Java, .NET, Mapping node and XSL. It is through these technologies that the input message is processed and the tree for the output message is produced. The cost of running this is dependent on the amount and complexity of the transformation processing that is coded.

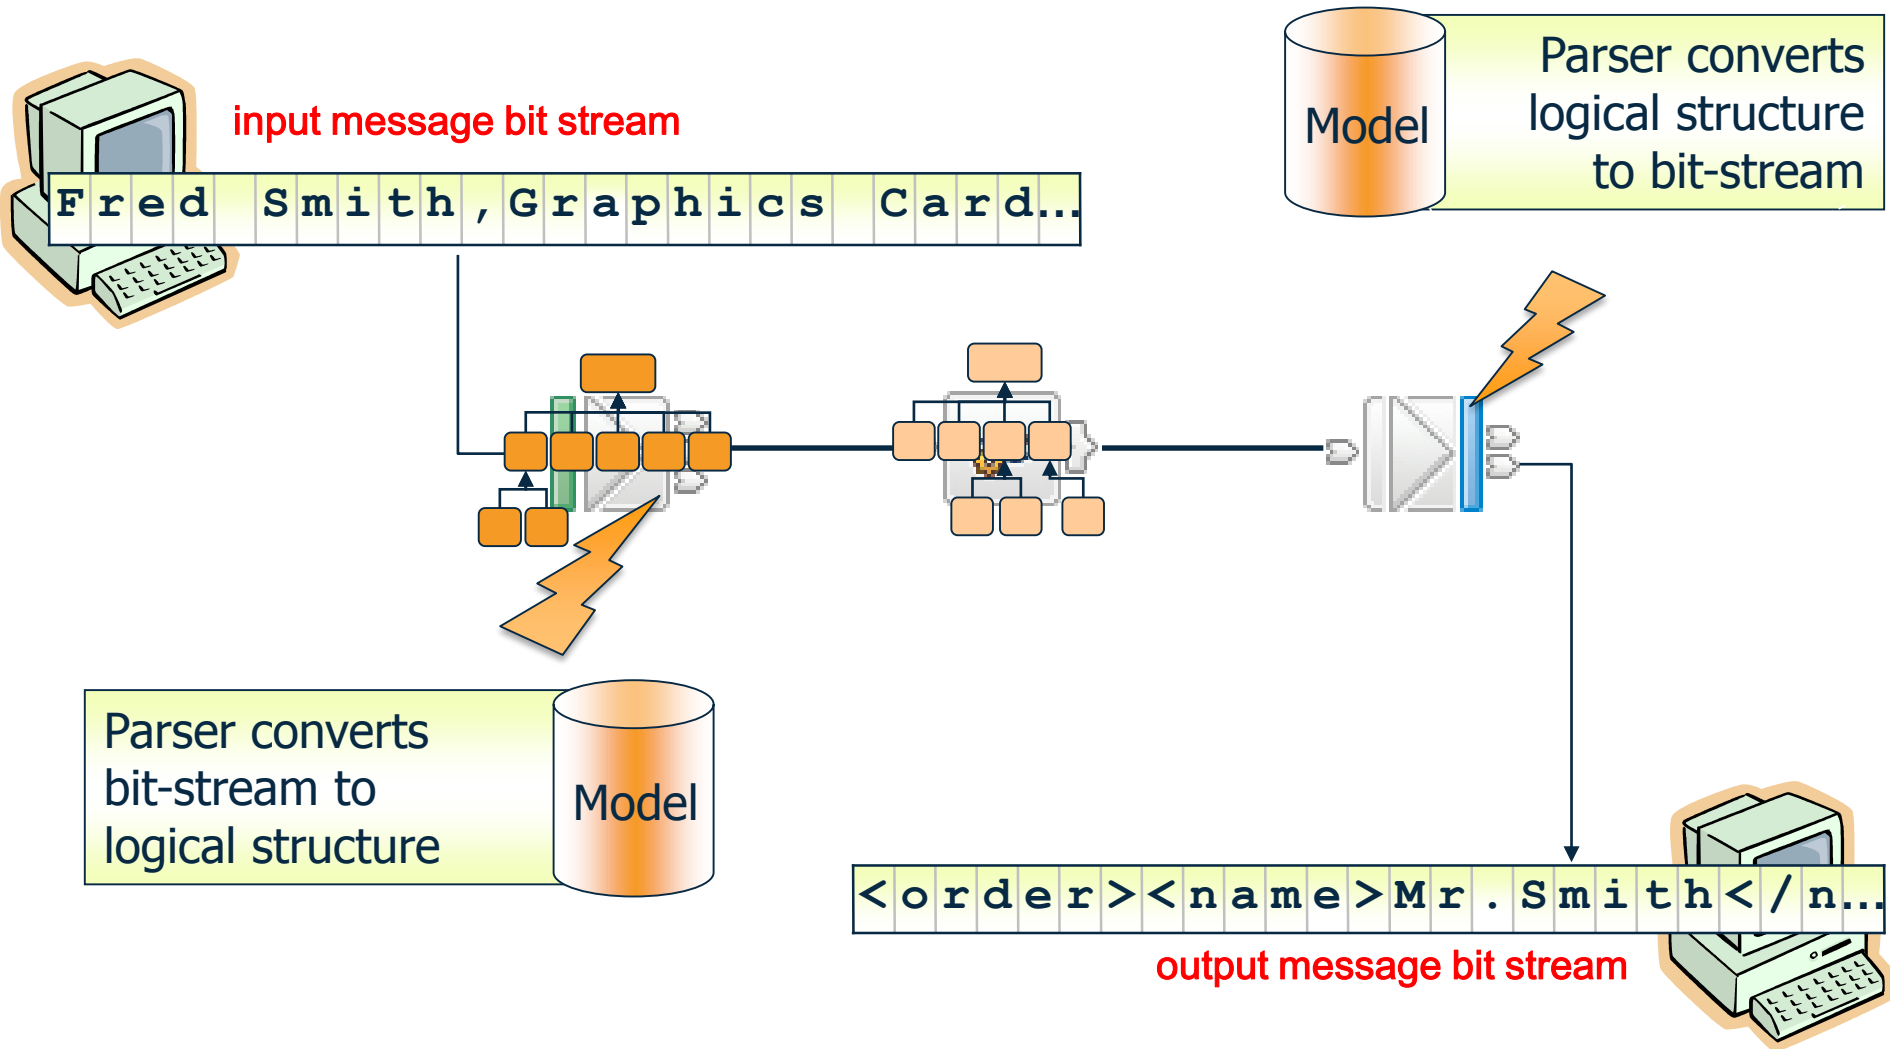

Notes for slide 5 (2 of 2)

- **Navigation.** This is the process of "walking" the message tree to access the elements which are referred to in the ESQL, Java, .NET , etc. The cost of navigation is dependent on the complexity and size of the message tree which is in turn dependent on the size and complexity of the input messages and the complexity of the processing within the message flow.
- **Tree Copying.** This occurs in nodes which are able to change the message tree such as Compute nodes. A copy of the message tree can be taken for recovery reasons so that if a compute node makes changes and processing in node incurs or generates an exception the message tree can be recovered to a point earlier in the message flow. Without this a failure in the message flow downstream could have implications for a different path in the message flow. The tree copy is a copy of a structured object and so is relatively expensive. It is not a copy of a sequence of bytes. For this reason it is best to minimize the number of such copies, hence the general recommendation to minimize the number of compute nodes in a message flow. Tree copying does not take place in a Filter or Database node for example since ESQL normally only references the data in the message tree and does not update it.
- **Resources.** This is the cost of invoking resource requests such as reading or writing WebSphere MQ messages or making database requests. The extent of these costs is dependent on the number and type of the requests.

The parsing, navigation and tree copying costs are all associated with the population, manipulation and flattening of the message tree and will be discussed together a little later on.

Knowing how processing costs are encountered puts you in a better position to make design decisions which minimize those costs. This is what we will cover during the course of the presentation.

Parsers

Complete your session evaluations online at www.SHARE.org/Orlando-Eval

Notes for slide 8

- On the previous slide we saw that objects called “message trees” are sent to a node’s input terminals, and either the same or different message tree is propagated from a node’s output terminals.
- The message tree is a logical definition of a message processed by the broker. It’s described as a tree because messages are typically hierarchical in structure; a good example of this is XML. Other message formats too, are also often derived from complex structures which themselves can be derived from complex structures, and so on, which gives them a tree-like shape with leaf nodes representing simple data types.
- In IBM Integration Bus, parsers have the job of converting between physical messages (bit-streams) and logical trees. When a message arrives at the broker through an input node, the message bit-stream is converted into a tree structure by the parser, which typically uses a model to drive the form of the logical tree. Built-in parsers handle well known headers within the message (MQMD, MQRFH2 etc.). Finally the user data is parsed into the tree using the domain parser as identified in the MQRFH2 (or input node). Message Broker’s built-in parsers support multiple domains (MRM, SOAP, XMLNSC, Data Object, XMLNS, JMSMap, JMSStream, MIME, IDOC, BLOB and XML) to enable parsing of user and industry standard formats.
- As the logical tree is passed from node to node, the form of the logical tree may change depending on what the node is doing.
- When the message arrives at an output node, the parser converts the logical tree back into a physical bit-stream where it can be output to the external resource, where it can be read by the target (receiving) application. However, note that an output node need not indicate the end of a flow; it is possible to output to multiple destinations within a single invocation of a message flow. In this case, the logical tree can be passed on to other nodes and manipulated further, even after it has been converted back into a physical bit-stream for this particular output node.

Parsing

- The means of populating and serializing the tree
 - Can occur whenever the message body is accessed
 - Multiple parsers available: XMLNSC, DFDL, JSON, MRM XML, CWF, TDS, MIME, HTTP Headers, JMSMap, JMSStream, BLOB, IDOC, RYO
 - Message complexity varies significantly ...and so do costs!
- Several ways of minimizing parsing costs
 - Use cheapest parser possible
e.g. XMLNSC for XML, DFDL for non XML
 - Identify the message type quickly
 - Use parsing strategies
 - Parsing avoidance
 - Partial parsing
 - Opaque parsing

Notes for slide 10 (1 of 2)

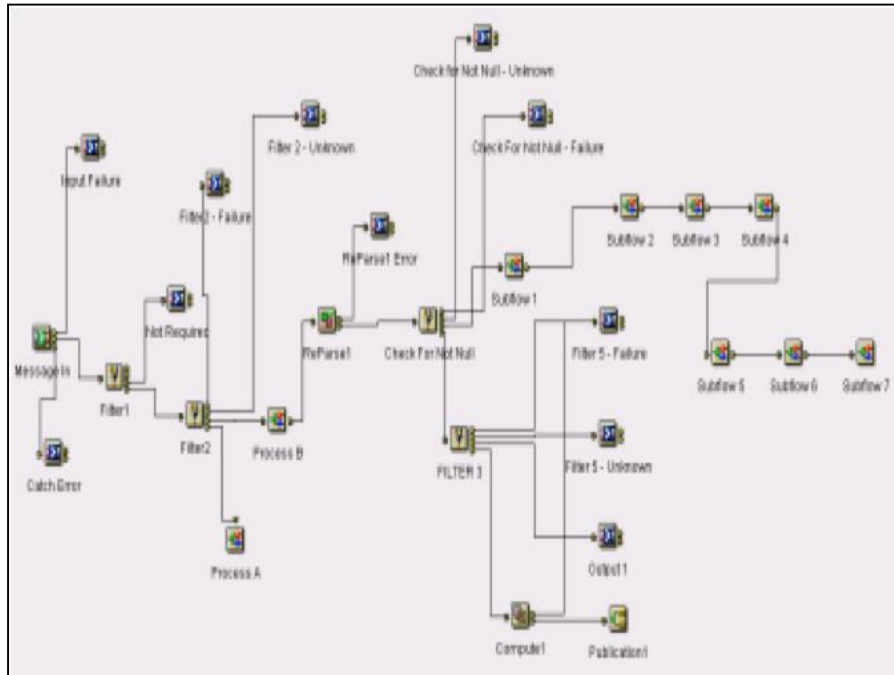

- In order to be able to process a message or piece of data within IBM Integration Bus we need to be able to model that data and build a representation of it in memory. Once we have that representation we can transform the message to the required shape, format and protocol using transformation processing such as ESQL, Java or .NET. That representation of a sequence of bytes into a structured object is the message tree. It is populated through a process called parsing.
- There are two parts to parsing within IBM Integration Bus:
 - The first is the most obvious. It is the reading and interpretation of the input message and recognition of tokens within the input stream. Parsing can be applied to message headers and message body. The extent to which it is applied will depend on the situation. As parsing is an expensive process in CPU terms it is not something that we want to automatically apply to every part of every message that is read by a message flow. In some situations it is not necessary to parse all of an incoming message in order to complete the processing within the message flow. A routing message flow may only need to read a header property such as user identifier or ApplIdentifyData in the MQMD for example. If the input message is very large parsing the whole message could result in a large amount of additional CPU being unnecessarily consumed if that data is not required in the logic of the message flow.
 - The second, is the flattening, or serialisation of a message tree to produce a set of bytes which correspond to the wire protocol of a message in the required output format and protocol.

Notes for slide 10 (2 of 2)

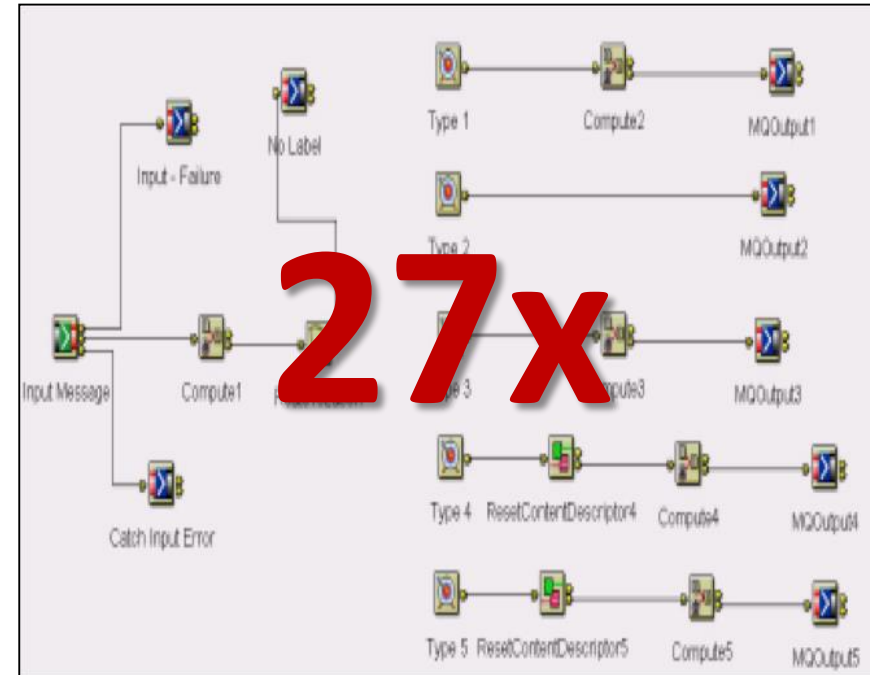

- IBM Integration Bus provides a range of parsers. Some of the parsers are named on the chart. The parsers cover different message formats. There is some overlap – XMLNSC and MRM XML are both able to parse a generic XML message but there are also differences. Other parsers such as JMSStream are targeted at specific message formats. In this case it is a JMS stream message. Data Format Description Language (DFDL) is a modelling language from the Open Grid Forum, and is the newest parser in IBM Integration Bus. It can be used to model non-XML messages.
- Messages vary significantly in their format and the level of complexity which they are able to model. Tagged Delimited string (TDS) messages for example can support nested groups. More complex data structures make parsing costs higher. The parsing costs of different wire formats is different. You are recommended to refer to the performance reports in order to get information on the parsing costs for different types of data.
- Whatever the message format there are a number of techniques that can be employed to reduce the cost of parsing. We will now look at the most common ones. First though we will discuss the reasons for the different cost of parsing.

Identifying the message type quickly

- Avoid multiple parses to find the message type

vs.

Notes for slide 13

- It is important to be able to correctly recognise the correct message format and type as quickly as possible. In message flows which process multiple types of message this can be a problem. What often happens is that the message needs to be parsed multiple times in order to ensure that you have the correct format. Dependent on the particular format and the amount of parsing needed this can be expensive.
- This example shows how a message flow which processed multiple types of input message was restructured to provide a substantial increase in message throughput.
- Originally the flow was implemented as a flow with a long critical path. Some of the most popular messages were not processed until late in the message flow resulting in a high overhead. The flow was complex. This was largely due to the variable nature of the incoming messages, which did not have a clearly defined format. Messages had to be parsed multiple times.
- The message flow was restructured. This substantially reduced the cost of processing. The two key features of this implementation were to use a very simple message set initially to parse the messages and the use of the RouteToLabel and Label nodes within the message flow in order to establish processing paths which were specialized for particular types of message.
- Because of the high processing cost of the initial flow it was only possible to process a small number of non persistent message per second using one copy of the message flow. With the one copy of the restructured flow it was possible to process 27x the original number of messages persistent messages per second on the same system. This is a 27 times increase in message throughput plus persistent messages where now being processed whereas previously they were non persistent.

Parser avoidance

- If possible, avoid the need to parse at all!
 - Consider only sending changed data
 - Promote/copy key data structures to MQMD, MQRFH2 or JMS Properties
 - May save having to parse the user data
 - Particularly useful for message routing
 - Model only what you need!

Notes for slide 15

- One very effective technique to reduce the cost of parsing is not to do it. A couple of ways of doing this are discussed in this foil.
- The first approach is to avoid having to parse some parts of the message. Suppose we have a message routing message flow which needs to look at a field in order to make a routing decision. If that field is in the body of the message the body of the incoming message will have to be parsed to get access to it. The processing cost will vary dependent on which field is needed. If it is field A that is OK as it is at the beginning of the body and would be found quickly. If it is field Z then the cost could be quite different, especially if the message is several megabytes in size. A technique to reduce this cost would be to have the application which creates this message copy the field that is needed for routing into a header within the message, say in an MQRFH2 header for an MQ message or as a JMS property if it is a JMS message. If you were to do this it would no longer be necessary to parse the message body so potentially saving a large amount of processing effort. The MQRFH2 or JMS Properties folder would still need to be parsed but this is going to be smaller amount of data. The parsers in this case are also more efficient than the general parser for a message body as the structure of the header is known.
- A second approach to not parsing data is to not send it in the first place. Where two applications communicate consider sending only the changed data rather than sending the full message. This requires additional complexity in the receiving application but could potentially save significant parsing processing dependent on the situation. This technique also has the benefit of reducing the amount of data to be transmitted across the network.

Partial parsing

- Typically, elements are parsed up to and including the required field
 - Elements that are already parsed are not reparsed
- If possible, put important elements nearer the front of the user data

Set MyVariable = <Message Element **Z**>

VS.

Typical Ratio of CPU Costs	1K msg	16K msg	256K msg
Filter First	1	1	1
Filter Last	1.4	3.4	5.6

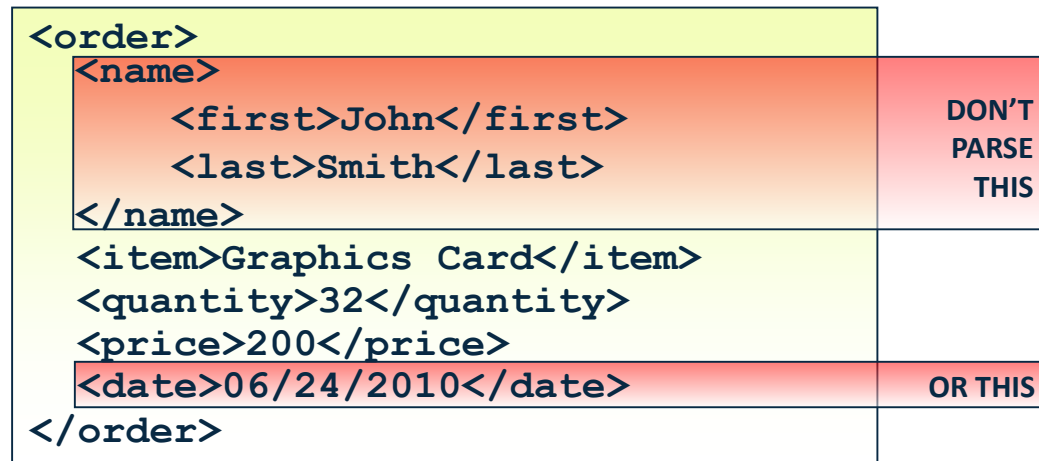

- Given parsing of the body is needed the next technique is to only parse what is needed rather than parse the whole message just in case. The parsers provided with IBM Integration Bus all support partial parsing.
- The amount of parsing which needs to be performed will depend on which fields in a message need to be accessed and the position of those fields in the message. We have two examples here. One with the fields ordered Z to A and the other with them ordered A to Z. Dependent on which field is needed one of the cases will be more efficient than the other. Say we need to access field Z then the first case is best. Where you have influence over message design ensure that information needed for routing for example is placed at the start of the message and not at the end of the message.
- As an illustration of the difference in processing costs consider the table in the foil. The table shows a comparison of processing costs for two versions of a routing message flow when processing several different message sizes.
 - For the filter first test the message flow routes the message based on the first field in the message. For the filter last the routing decision is made based on the last field of the message.
 - The CPU costs of running with each message size have been normalised so that the filter first test for each message represents a cost of 1. The cost of the filter last case is then given as a ratio to the filter first cost for that same message size.
 - For the 1K message we can see that by using the last field in the message to route the CPU cost of the whole message flow was 1.4 times the cost of using the first field in the same message. This represents the additional parsing which needs to be performed to access the last field.
 - For the 16K message, the cost of using the last field in the message had grown to 3.4 times that of the first field in the same message. That is we can only run at one third of the message that we can when looking at the first field of the message.
 - These measurements were taken on a pSeries 570 Power 5 with 8 * 1.5 GHZ processors, using WebSphere Message Broker V6.

Notes for slide 17 (2 of 2)

- For the 256K message, the cost of using the last field in the message was 5.6 times that of the first field in the same message. That is we can only run at one fifth of the message that we can when looking at the first field of the message.
- You can see how processing costs quickly start to grow and this was a simple test case. With larger messages the effect would be even more pronounced. Where the whole message is used in processing this is not an issue as all of the data will need to be parsed at some point. For simple routing cases though the ordering of fields can make a significant difference.
- When using ESQL the field references are typically explicit. That is we have references such as InputRoot.Body.A. IBM Integration Bus will only parse as far as the required message field to satisfy that reference. It will stop at the first instance. When using XPath, which is a query language the situation is different. By default an XPath expression will search for all instances of an element in the message which implicitly means a full parse of the message. If you know there is only one element in a message there is the chance to optimise the XPath query to say only retrieve the first instance. See the ESQL and Java coding tips later in the presentation for more information.

Opaque parsing

- Treat elements of an XML document as an unparsed BLOB
- Reduces message tree size and parsing costs
- Cannot reference the sub tree in message flow processing
- Configured on input nodes (“Parser Options” tab)

- Opaque parsing is a technique that allows the whole of an XML sub tree to be placed in the message tree as a single element. The entry in the message tree is the bit stream of the original input message. This technique has two benefits:
 - It reduces the size of the message tree since the XML sub tree is not expanded into the individual elements.
 - The cost of parsing is reduced since less of the input message is expanded as individual elements and added to the message tree.
- Use opaque parsing where you do not need to access the elements of the sub tree, for example you need to copy a portion of the input tree to the output message but may not care about the contents in this particular message flow. You accept the content in the sub folder and have no need to validate or process it in any way.
- Opaque parsing is supported for the XMLNS and XMLNSC domains only.
- The support for the XMLNS domain continues to be available in its original form. Indeed this is the only way in which the messages in the XMLNS domain can be opaquely parsed. It is not possible to use the same interface that is provided for the XMLNSC to specify element names for the XMLNS domain.
- The following pages of notes explain how opaque parsing is performed for messages in the XMLNS and XMLNSC domains.

Notes for slide 20 (2 of 2)

- The message domain must be set to XMLNSC.
- The elements in the message which are to be opaquely parsed are specified on the 'Parser Options' page of the input node of the message flow. See the picture below of the MQInput node.
- Enter those element names that you wish to opaquely parse in the 'Opaque Elements' table.
- Be sure not to enable message validation as it will automatically disable opaque parsing. Opaque parsing in this case does not make sense since for validation the whole message must be parsed and validated.
- Opaque parsing for the named elements will occur automatically when the message is parsed.
- It is not currently possible to use the CREATE statement to opaquely parse a message in the XMLNSC domain.

Navigation

- The logical tree is walked every time it is evaluated
 - This is not the same as parsing!

SET Description =

```
InputRoot.XMLNSC.Body.Level1.LevelX.Description.Line[count];
```

- Long paths are inefficient
 - Minimise their usage, particularly in loops
 - Use reference variables / pointers (ESQL / Java / .NET)
 - Build a smaller message tree if possible
 - Use compact parsers (XMLNSC, RFH2C)
 - Use opaque parsing

- Navigation is the process of accessing elements in the message tree. It happens when you refer to elements in the message tree in the Compute, JavaCompute, .NET and Mapping nodes.
- The cost of accessing elements is not always apparent and is difficult to separate from other processing costs.
- The path to elements is not cached from one statement to another. If you have the ESQL statement
`SET Description = Root.Body.Level1.Level2.Level3.Description.Line[1],`
the runtime will access the message tree starting at the correlation Root and then move down the tree to Level1, then Level2, then Level3, then Description and finally it will find the first instance of the Line array. If you have this same statement in the next line of your ESQL module exactly the same navigation will take place. There is no cache to the last referenced element in the message tree. This is because access to the tree is intended to be dynamic to take account of the fact that it might change structure from one statement to another. There are techniques available though to reduce the cost of navigation.
- With large message trees the cost of navigation can become significant. There are techniques to reduce which you are recommended to follow:
 - Use the compact parsers (XMLNSC, MRM XML and RFH2C). The compact parsers discard comments and white space in the input message. Dependent on the contents of your messages this may have an effect of not. By comparison the other parsers include data in the original message, so white space and comments would be inserted into the message tree.
 - Use reference variables if using ESQL or references if using Java/.NET. This technique allows you to save a pointer to a specific place in the message tree. Say to `Root.Body.Level1.Level2.Level3.Description` for example.
- For an example of how to use reference variables and reference pointers see the coding tips given in the Common Problems section.

Message tree copying

- Message tree copying causes the logical tree to be duplicated in memory... and this is computationally expensive
- Reduce the number of times the tree is copied
 - Reduce the number of Compute nodes in a message flow
 - Copy at an appropriate level in the tree (copy once rather than for multiple branch nodes)
 - Copy data to the Environment (although changes are not backed out)
- Minimize the effect of tree copies
 - Produce a smaller message tree (again)!

```
SET OutputRoot.XMLNSC.A = InputRoot.XMLNSC.A;
```

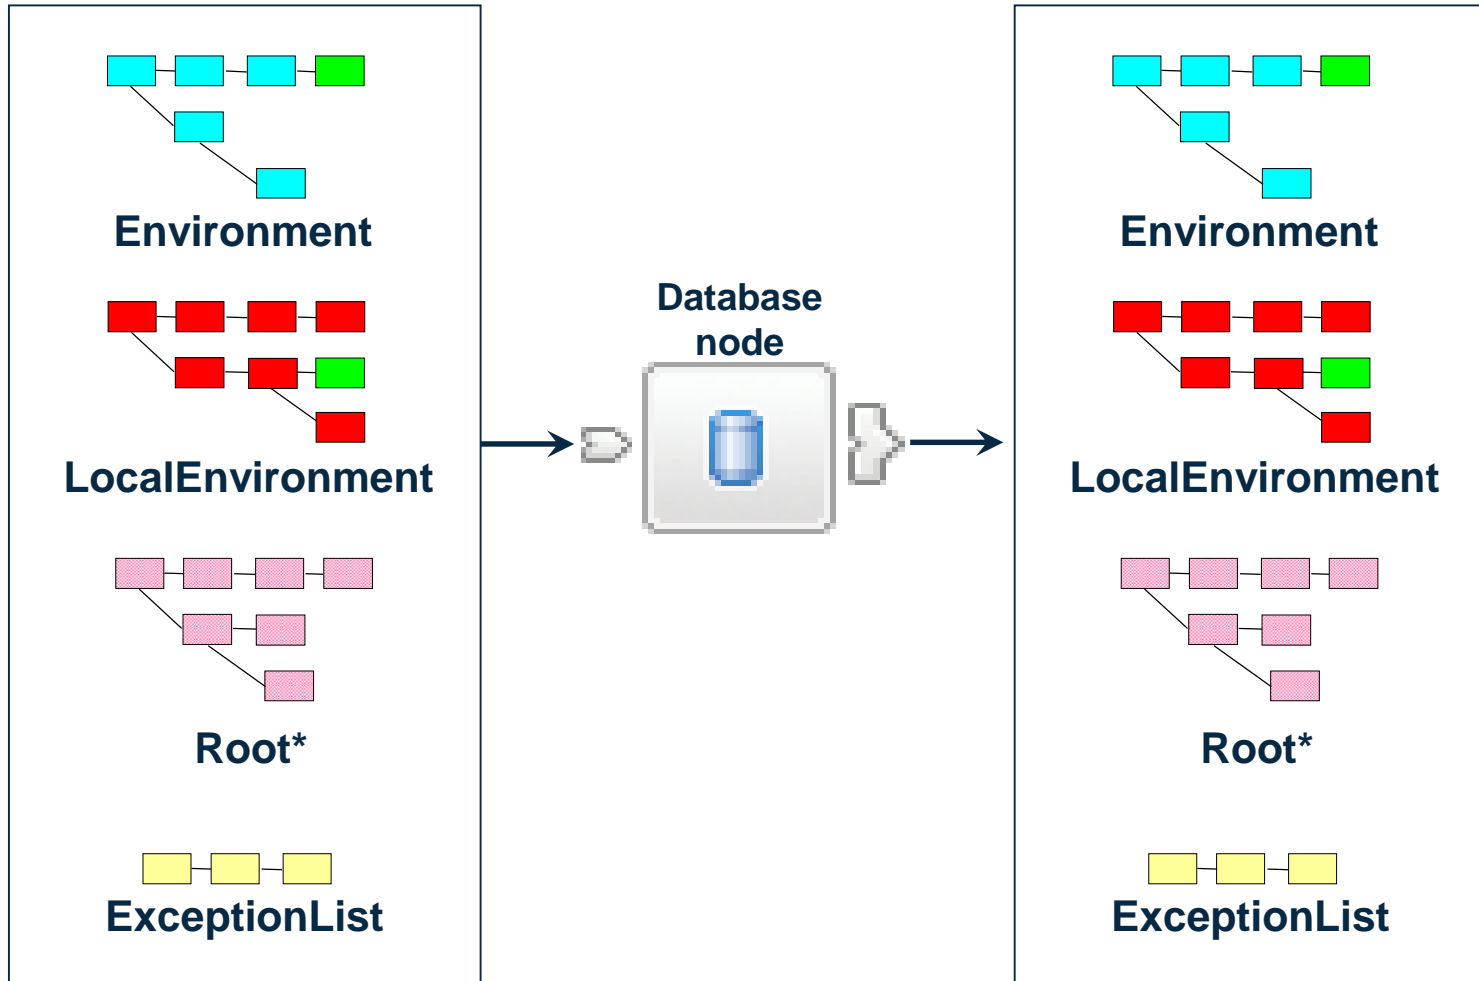

Notes for slide 25 (1 of 2)

- Tree Copying is the process of copying the message tree either in whole or part.
- Copying occurs in nodes which are able to change the message tree such as Compute nodes. A copy of the message tree can be taken for recovery reasons so that if a compute node makes changes and processing in node incurs or generates an exception the message tree can be recovered to a point earlier in the message flow. Without this a failure in the message flow downstream could have implications for a different path in the message flow. The tree copy is a copy of a structured object and so is relatively expensive. It is not a copy of a sequence of bytes. For this reason it is best to minimize the number of such copies, hence the general recommendation to minimize the number of compute nodes in a message flow. Tree copying does not normally take place in a Filter node for example since ESQL only references the data in the message tree and does not update it.
- There are a few ways to reduce the costs of tree copying. These are:
 - Produce a smaller message tree in the first place. A smaller tree will cost less to copy. Ways to achieve this are to use Smaller messages, use Compact Parsers (XMLNSC, MRM XML, RFH2C), use Opaque parsing partial parsing (all discussed previously).
 - Reduce the number of times the whole tree is copied. Reducing the number of compute nodes will help to reduce the number of times that the whole tree needs to be copied. In particular avoid situations where you have one compute node followed immediately by another. In many cases you may need multiple computes across a message flow. What we want to do is to optimise the processing not have to force everything into one compute node.
 - Copy portions of the tree at the branch level if possible rather than copying individual leaf nodes. This will only work where the structure of the source and destination are the same but it is worth doing if possible.

Notes for slide 25 (2 of 2)

- Copy data to the Environment correlation (remember it is not backed out) and work with it in Environment. This way the message tree does not have to be copied every time you run a compute node. Environment is a scratchpad area which exists for each invocation of a message flow. The contents of Environment are accessible across the whole of the message flow. Environment is cleared down at the end of each message flow invocation.
 - The first compute node in a message flow can copy InputRoot to Environment. Intermediate nodes then read and update values in the Environment instead of using the InputRoot and OutputRoot correlations as previously.
 - In the final compute node of the message flow OutputRoot must be populated with data from Environment. The MQOutput node will then serialize the message as usual. Serialization will not take place from Environment.
- Whilst use of the Environment correlation is good from a performance point of view be aware that the any updates made by a node which subsequently generates an exception will remain in place. There is no back-out of changes as there is when a message tree copy was made prior to the node exception.
 - You also need to remember to create a parser for the target of the copy into the Environment as one is not created automatically.

Example of avoiding a tree copy

The screenshot displays a graphical user interface for IBM Integration Designer. On the left, a 'Palette' lists various components like Selection, Connection, Favorites, WebSphere MQ, JMS, HTTP, Routing, Transformation, Construction, Database, Validation, Timer, Additional Protocols, and TCP/IP nodes. The main workspace shows a flow with three parallel paths. Each path starts with a 'Read Q' node, followed by a 'Check Version' node, then a 'Compute' node (labeled 'Compute 101', 'Compute 100', and 'Compute 102' respectively), an 'HTTP Req' node, a 'Response' node, and finally an 'MQReply' node. The 'Check Version' node in the first path is highlighted with a red box. Below the workspace, the 'Properties' window is open for the 'Compute Node' of the 'Check Version' node. The 'Compute Node' dropdown menu is expanded, showing 'LocalEnvironment' selected and circled in red. A red arrow points from the 'Check Version' node in the workspace to the 'LocalEnvironment' selection in the dropdown menu.

```
-- Set the version numbers this flow supports
SET Environment.SupportedVersions = '0102 0101 0100';

-- getMessageVersion returns label name for the message version (for example, '0102')
PROPAGATE TO LABEL 'V' || getMessageVersion(Environment, InputRoot, TRUE);

-- PROPAGATE already passed the message; do not propagate to "Out"
RETURN FALSE;
```

The Do's and Don'ts of IBM Integration Bus Performance

8/11/2015

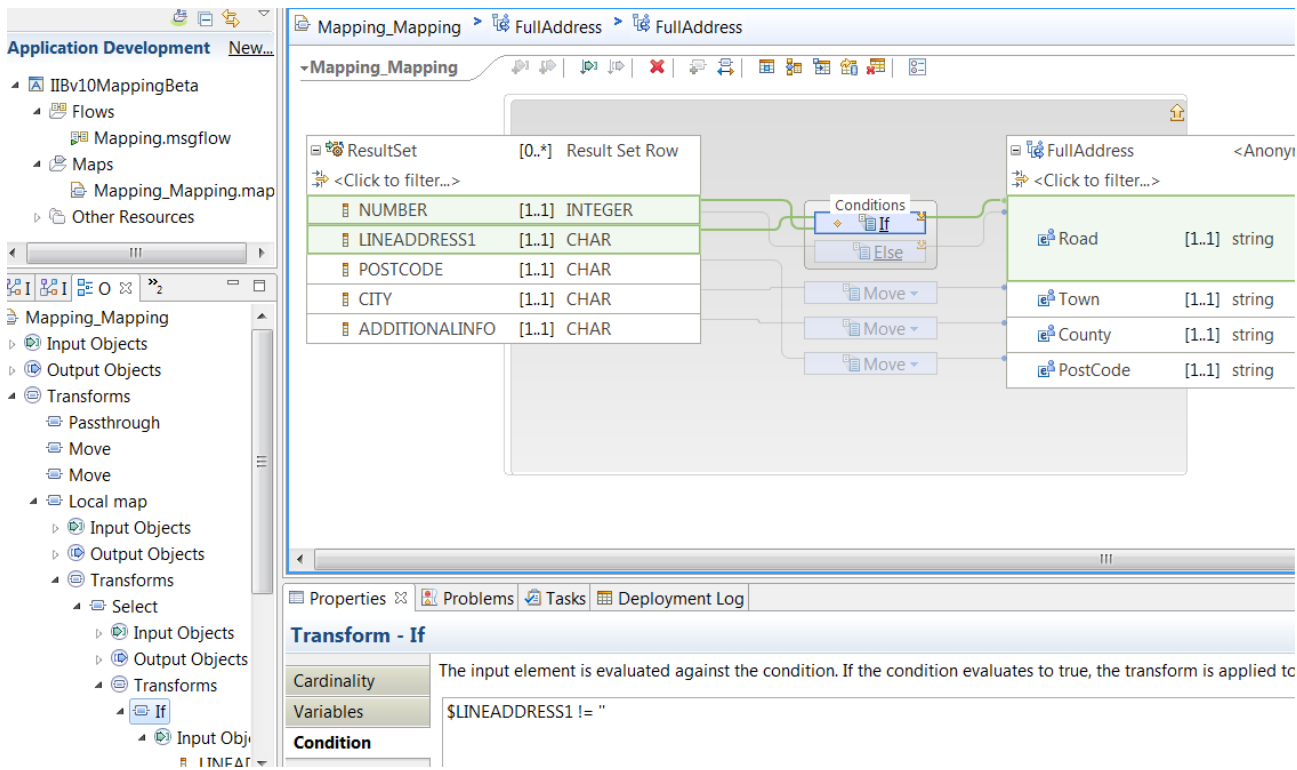

SHARE
in Orlando 2015

Notes for slide 32

- This foil shows one case where it was possible to avoid a tree copy. You may be able to use this same technique in other situations.
- The purpose of the message flow is to read MQ messages, determine the message type and route to the appropriate type of processing. There are three legs of processing, each starting with a Label node (V0100, V0101 & V0102).
- The compute node Check_Version issues a PROPAGATE to the appropriate label node dependent on a field in the incoming message. The message version information is obtained from the incoming message by a function called getMessageVersion. The ESQL on the foil shows how this is done.
- As processing at this point is limited to routing only there is no need for Check_Version to modify the incoming message tree and as such a value of LocalEnvironment is sufficient for the Compute Mode of the node. Had a value of LocalEnvironment and Message been selected then we would have needed to copy the message tree which would have increased processing costs, unnecessarily in this case.

Graphical data transformation - Overview

- Graphical data maps offer the ability to achieve the transformation of a message without the need to write code, providing a visual image of the transformation, and simplifying its implementation and ongoing maintenance.
- A message map is the IBM Integration Bus implementation of a graphical data map. It is based on XML schema and XPath 2.0 standards.

Complete your session evaluations online at www.SHARE.org/Orlando-Eval

Notes for slide 34

- Graphical Data mapping editor included since WebSphere Message Broker v8
- Graphical data maps are known as message maps in IIB
- In the Graphical Data Mapping editor a user can do:
 - Transform a message: You can use a message map to graphically transform a message assembly, message body, and properties, according to the transforms and XPath functions defined in the message map. You can use the full set of XPath 2.0 expressions and functions to implement data calculations and manipulations in a message map. To define the input and output messages to a map, you can use a schema base message model, which defines the structure of the data and provides information about the data type, or you can define it dynamically in the map by using the Add user defined function.
 - Enrich a message with data available in an external database: You can use a message map to enrich, or conditionally set the output message with data from a database table. The table data structure must be defined to the message map, and an SQL where clause can be used to select specific rows. The resulting row data is presented as an extra input in the message map, according to the database schema.
 - Modify data located in an external database.
 - Route a message based on content: You can use a message map to graphically route a message. You can modify the local environment tree to set a dynamic message destination.
- <https://developer.ibm.com/integration/docs/ibm-integration-bus/get-started/get-started-gdm/>

Graphical data transformation - cardinality

The data model of your input and output message determines the required processing and hence impacts the performance of a graphical map (message map)

- set the cardinality of each element in a data model to specific values whenever possible.
- only configure for maximum flexibility when actually required.
- only set *minOccurs* to 0, when an element needs to be optional
- only set *maxOccurs* above 1 if the element will actually repeat

The Graphical Data Mapping runtime engine will check all the possible options that you configured during development. Only configure the instances that are required to calculate the output value.

```

Graphical data transformation – nil values

- The data model of your input and output message determines the required processing and hence impacts the performance of a graphical map (message map)
- Only define an element as nillable when you know that the application will need to handle out of bound value in the data.
- Note defining an output element as mandatory, cardinality minOccurs > 1 and nillable means that the output will be created as nilled if there is no input mapping or the input mapping produces no value
- See https://www.ibm.com/developerworks/community/blogs/c7e1448b-9651-456c-9924-f78bec90d2c2/entry/gaphical_data_mapping_blog_draft_1_designing_a_message_map

avoid!

Graphical data transformation - Validation

- The data model of your input and output message determines the required processing and hence impacts the performance of a graphical map (message map)
- Enable schema validation when you are developing a map. Disable validation in your test and production systems unless the solution requires validation enabled.
- Validation is the process of checking a message's structure, and optionally the values within, based on a description called a schema.
- Message validation can be enabled directly on a number of input nodes such as the MQInput, and SOAPInput nodes.
- Validation adds an overhead when processing messages at run time.
- (https://www.ibm.com/developerworks/community/blogs/c7e1448b-9651-456c-9924-f78bec90d2c2/entry/benefits_of_message_validation_when_using_mapping_nodes)

Notes for slides 34 – 38 (1 of 2)

- Identify the input and output components to a message map. You can select an XML schema, DFDL schema, or message set to define the message body
- You can also include the headers and folders of the Message Assembly when you need to read data or write data from these:
- To read elements of input headers or folders, add them to the input message assembly only. The Graphical Data Mapping editor passes to the output the input header or folder unchanged.
- To modify elements of an input header or folder, add them to the input message assembly and to the output message assembly. Then, define transforms between the elements.
- To initialize an output header or folder, that is, to create a new header or folder in your output message, add it only to the output message assembly. Then define transforms to set its data.
- To delete an input header or folder from the output message, add the component to the output message assembly and do not set any field.
- Remember only add header or folder at the output if you need to modify it's content
- Having a header or folder on input and output with only a move between them still causes the mapping node to create and rewrite the header or folder.

- The function of a message map is driven by the data models that define the input and the output message structures of a map. At run time, the Graphical Data Mapping engine must account for all possible states of the data when executing the transformations you have defined in the map against the data models. You may have control or not over the data models in your solution. If you can influence the data model, these are some of the key points to consider:
- 1.- Set the cardinality of each element in a data model to specific values whenever possible. When you define a logical model, you can configure the cardinality of each element by setting the minoccurs and the maxoccurs properties.
- **Avoid, whenever possible, configuring maximum flexibility unless actually required. Only set minoccurs to 0, when an element needs to be optional. Only set maxoccurs above 1 if the element will actually repeat.**
- 2.- Define an element as nillable when you know that the application will need to handle out of bound value in the data.
- 3.- Enable schema validation when you are developing a map. Disable validation in your test and production systems unless the solution requires validation enabled. Validation is the process of checking a message's structure, and optionally the values within, based on a description called a schema. The Mapping node relies on schema definitions, but it does not enforce them. If the input message does not conform to the schema being used, the output you expect to see might not be produced. During the development of your integration solutions, it is recommended that you enable validation. However, for other environments such as test or production, you should only leave validation on if your solution requires it because of the extra processing involved.

Graphical data transformation: transforms

Transform - Custom XPath

General: The input element is evaluated against the condition. If the condition evaluates to true, the transform is applied to the input element.

Namespaces: <Type an XPath expression here. Content assist available (Ctrl+space)>

Cardinality

Variables

Condition

Sort

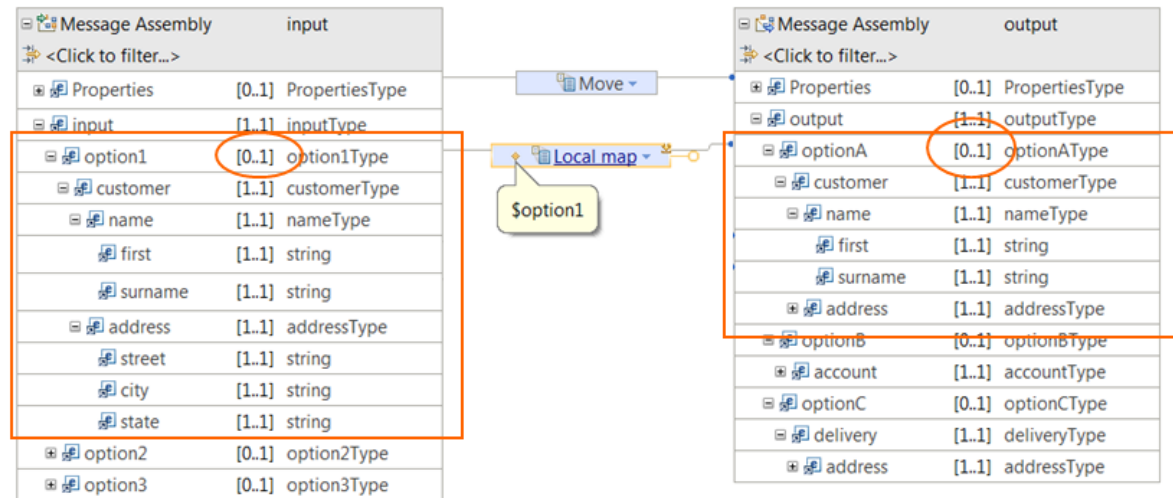

For each output element, identify the transform and the input elements required to calculate its value.

- When the transformation of an element from input to output becomes more than just a simple Move, or type conversion (xs:type), you can call on the full set of standard XPath 2.0 operators and functions to manipulate the data as required.
 - When you need to process data, rather than just move it from source to target, use custom transforms to define specialized transformations.
 - Define a conditional expression for each transform to determine at run time whether the transform is applied or not.
- From a performance point of view, it is recommended that you use XPath transforms or the Custom XPath transform as your first choice, then Custom Java. You can also use Custom ESQL.

Graphical data transformation: structural transforms

Use the 'Local map' transform to map complex source to complex target

If elements are optional, set a condition property so that you only create an output if the input exists

Use structural transforms to enhance the readability, maintenance, and performance of your map

- Use structural transforms such as Local Map or Submap to group transforms that require the same condition to determine whether they are applied in a map at run time
- At runtime:
 - If the condition evaluates to true, you obtain similar performance results whether all the transforms are in the main map or grouped into nested maps that are associated with structural transforms. However, you obtain a more readable map.
 - If the condition evaluates to false, the Graphical Data Mapping editor ignores this group of transforms.

Structural transform: for each

Structural transform: mapping override

Transforms contained in a mapping overrides group are applied after a parent transform is applied. This function enables you to copy a complex type from the input to the output object, while updating some of the child elements in the complex type.

The Mapping override feature allows you to copy a complex type and modify some of its output elements without having to define a transform for each output element. Hence, you get better performance and a more readable map.

Resource Access

MQ

- tune the QM and associated QM's, logs, buffer sizes (see the WebSphere MQ performance reports)
- avoid unnecessary use of persistent messages, although always use persistent messages as part of a co-ordinated transaction
- use fast storage if using persistent messages
- http://www.ibm.com/developerworks/websphere/library/techarticles/0712_dunn/0712_dunn.html

JMS

- follow MQ tuning if using MQ JMS
- follow provider instructions
- http://www.ibm.com/developerworks/websphere/library/techarticles/0604_bicheno/0604_bicheno.html

SOAP / HTTP

- Use persistent HTTP connections. You should always set this on the HTTPRequest node.
- use embedded integration server level listener for HTTP nodes (V7.0.0.1)
- http://www.ibm.com/developerworks/websphere/library/techarticles/0608_braithwaite/0608_braithwaite.html

File

- use cheapest delimiting option
- use fast storage

Database

- tune your DB – speak to your DBA

- There are a wide variety of ways of reading data into IBM Integration Bus and sending it out once it has been processed. The most common methods are MQ messages, JMS messages, HTTP and files. Collectively for this discussion let's refer to them as methods of transport although we recognise that is not completely accurate where file, VSAM and database are concerned.
- Different transports have different reliability characteristics. An MQ persistent message has assured delivery. It will be delivered once and once only. MQ non persistent messages are also pretty reliable but are not assured. If there is a failure of machine or power outage for example data will be lost with these non persistent messages. Similarly data received over a raw TCP/IP session will be unreliable.
- In some situations we are happy to accept the limitations of the transport in return for its wide availability or low cost for example. In others we may need to make good the shortcoming of the transport. One example of this is the use of a WebSphere MQ persistent message (or database insert) to reliably capture coming over a TCP/IP connection as the TCP/IP session is unreliable – hey this is why MQ is popular because of the value it builds on an unreliable protocol.
- As soon as data is captured in this way the speed of processing is changed. We now start to work at the speed of MQ persistent messages or the rate at which data can be inserted into a database. This can result in a significant drop in processing dependent on how well the queue manager or database are tuned.
- In some cases it is possible to reduce the impact of reliably capturing data if you are prepared to accept some additional risk. If it is acceptable to have a small window of potential loss you can save the data to an MQ persistent message or database asynchronously. This will reduce the impact of such processing on the critical path. This is a decision only you can make. It may well vary by case by case dependent on the value of the data being processed.

- It is important to think how data will be received into IBM Integration Bus. Will data be received one message at a time or will it arrive in a batch? What will be involved in session connection set-up and tear-down costs for each message or record that is received by the message flow. Thinking of it in MQ terms will there be an MQCONN, MQOPEN, MQPUT, MQCMT and MQDISC by the application for each message sent to the message flow. Lets hope not as this will generate a lot of additional processing for the integration bus queue manager [assuming the application is local to the queue manager]. In the HTTP world you want to ensure that persistent sessions (not to be confused with MQ persistence) are used for example so that session set-up and tear-down costs are minimised. Make sure that you understand the sessions management behaviour of the transport that is being used and that you know how to tune the transport for maximum efficiency.
- IBM Integration Bus give you the ability to easily switch transport protocols, so data could come in over MQ and leave the message flow in a file or be sent as a JMS message to any JMS 1.1 provider. In your processing you should aim to keep a separation between the transport used and the data being sent over that transport. This will make it easier to use different transports in the future.

Processing Logic

- Various options available
 - Java
 - ESQL
 - .NET
 - Mapping
 - XSL

- Performance characteristics of the different options is rarely an issue
 - Choose an option based on skills, ease-of-use and suitability for the scenario
- Think carefully before mixing transformation options in the same message flow

Notes for slide 48 (1 of 2)

- There are a number of different transformation technologies available with IBM Integration Bus. These are:
 - ESQL, an SQL like syntax, which runs in nodes such as the Compute, Filter and Database.
 - Java which runs in a JavaCompute node.
 - The Graphical Data Mapping node.
 - Extensible Stylesheets (XSL) running in an XML Transformation node. This provides a good opportunity to reuse an existing asset.
 - The .NET compute node routes or transforms messages by using any Common Language Runtime (CLR) compliant .NET programming language, such as C#, Visual Basic (VB), F# and C++/CLI (Common Language Infrastructure).
- As there is a choice of transformation technology this offers significant flexibility. All of these technologies can be used within the same message flow if needed.
- Different technologies will suit different projects and different requirements.

- Factors which you may want to take into account when making a decision about the use of transformation technology are:
 - The pool of development skills which is available. If developers are already skilled in the use of ESQL you wish continue using this as the transformation technology of choice. If you have a strong Java skills then the JavaCompute node may be more relevant, strong C# skills will make the .NET node more relevant, rather than having to teach your programmers ESQL.
 - The ease with which you could teach developers a new development language. If you have many developers it may be not be viable to teach all of them ESQL for example and you may only educate a few and have them develop common functions or procedures.
 - The skill of the person. Is the person an established developer, or is the mapping node more suitable.
 - Asset re use. If you are an existing user of Message Broker you may have large amounts of ESQL already coded which you wish to re-use. You may also have any number of resources that you wish to re-use such as Java classes for key business processing, stylesheets, or .NET assemblies. You want to use these as the core of message flow processing and extend the processing with one of the other technologies.
 - Performance is rarely an issue.
 - Think carefully before combining a lot of different transformation technologies within a path of execution of a message flow. ESQL, Java, .NET and Mapping node will happily intermix but there is an overhead in moving to/from other technologies such as XSL as they do not access the message directly. The message has to be serialised when it is passed to those other technologies and then the results parsed to build a new message tree.

Agenda

- What are the main performance costs inside message flows?

... and what are the best practices that will minimize these costs?

- What other performance considerations are there?
- Understanding your integration node's behavior

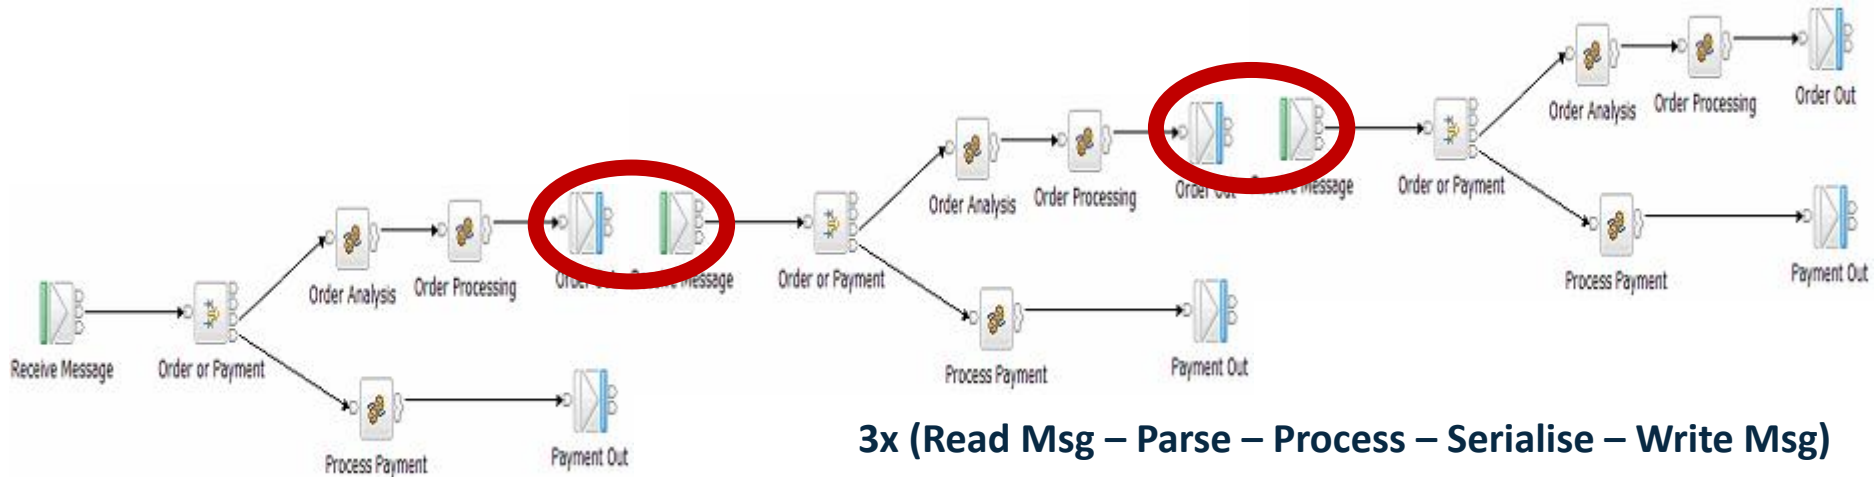

Consider the end-to-end flow of data

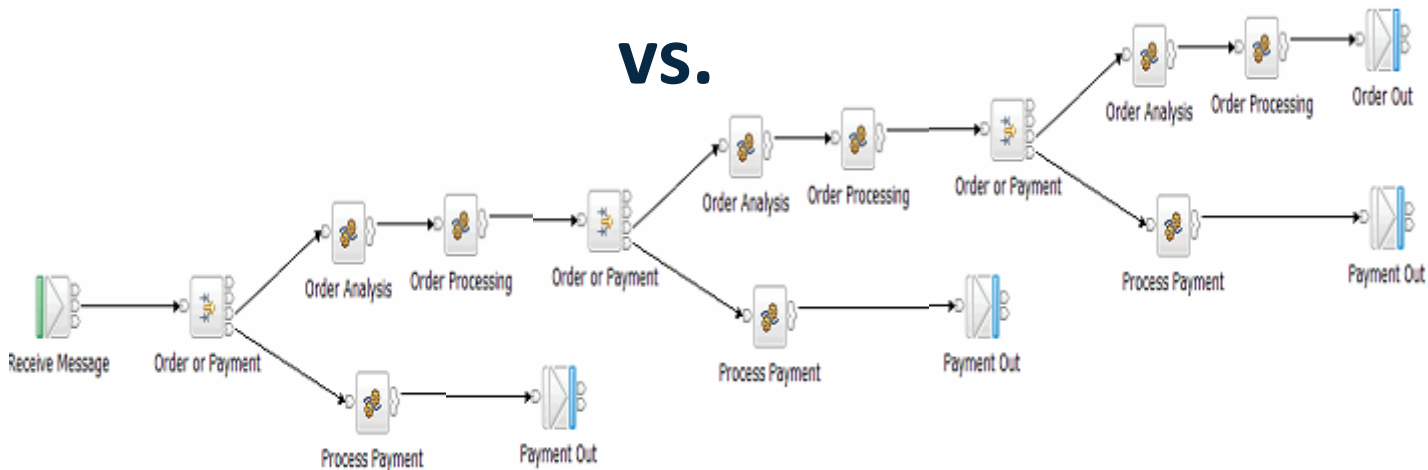

- Interaction between multiple applications can be expensive!
 - Store and Forward
 - Serialise ... De-serialise
- Some questions to ponder:
 - Where is data being generated? Where is data being consumed?
 - What applications are interacting in the system?
 - What are the interactions between each of these applications?
- And as data passes through the integration server:
 - Where are messages arriving? Where are they leaving?
 - Are multiple message flows being invoked?
 - Request/Reply?
 - Flow-to-flow?

Consider the sequencing of message flows

3x (Read Msg – Parse – Process – Serialise – Write Msg)

vs.

Read Msg – Parse – 3x (Process) – Serialise – Write Msg

- It is important to think about the structure of your message flows and to think about how they will process incoming data. Will one message flow process multiple message types or will it process a single type only. Where a unique message flow is produced for each different type of message it is referred to as a specific flow. An alternative approach is to create message flows which are capable of processing multiple message types. There may be several such flows, each processing a different group of messages. We call this a generic flow.
- There are advantages and disadvantages for both specific and generic flows.
 - With specific flows there are likely to be many different message flows. In fact as many message flows as there are types of input message. This does increase the management overhead which is a disadvantage. A benefit of this approach though is that processing can be optimized for the message type. The message flow does not have to spend time trying to determine the type of message before then processing it.
 - With the generic flow there is a processing cost over and above the specific processing required for that type of message. This is the processing required to determine which of the possible message types a particular message is. Generic flows can typically end up parsing an input message multiple times. Initially to determine the type and then subsequently to perform the specific processing for that type of message. A benefit of the generic flow is that there are likely to be fewer of them as each is able to process multiple message types. This makes management easier. Generic flows tend to be more complex in nature. It is relatively easy to add processing for another type of message though. With generic message flows it is important to ensure that the most common message types are processed first. If the distribution of message types being processed changes over time this could mean processing progressively becomes less efficient. You need to take account of this possibility in you message flow design. Use of the RouteToLabel node can help with this problem.

- There are advantages to both the specific and generic approaches. From a message throughput point of view it is better to implement specific flows. From a management and operation point of view it is better to use generic flows. Which approach you choose will depend on what is important in your own situation.
- To bring clarity to your message flow processing consider using the RouteToLabel node. It can help add structure and be effective in separating different processing paths with a message flow. Without flows can become long and unwieldy resulting in high processing costs for those messages with have a long processing path. See the two examples on the foil. Both perform the same processing but have different structures. One is clearly more readable than the other.
- There are several ways of achieving code reuse with IBM Integration Bus. They are subflows, ESQL procedures and functions, invoking external Java classes and calling a database stored procedure. There are some performance implications of using the different techniques which we will briefly look at.
- Subflows are a facility to encourage the reuse of code. Subflows can be embedded into message flows or deployed separately in v8 and above. There are no additional nodes inserted into the message flow as a result of using subflows. However be aware of implicitly adding extra nodes into a message flow as a result of using subflows. In some situations compute nodes are added to subflows to perform marshalling of data from one part of the message tree into a known place in the message tree so that the data can be processed by the message flow. The result may then be copied to another part of the message tree before the subflow completes. This approach can easily lead to the addition of two compute nodes, each of which performs a tree copy. In such cases the subflow facilitates the reuse of logic but unwittingly adds an additional processing head. Consider the use of ESQL procedures instead for code reuse. They provide a good reuse facility and the potential additional overhead of extra Compute nodes is avoided.

- Existing Java classes can be invoked from within a message flow using either ESQL or Java. The same is true for .NET applications which can also be called from ESQL in V8 and above.
 - From ESQL it is possible to declare an external function or procedure which specifies the name of the Java or .NET routine to be invoked.. Parameters (in,out, in-out) can be passed to the method.
 - From within a Java or .NET compute node the class can be invoked as any other class. You will need to ensure that the class file is accessible to the integration server runtime for this to work.
- A database stored procedure can be called from within ESQL by using an external procedure. It is also possible to invoke a stored procedure using a PASSTHRU statement but this is not recommended as it is not as capable as a procedure definition directly in ESQL.
- The cost of calling these external routines will vary and be dependent on what is being called (Java/.NET VS Stored procedure) and the number and type of parameters. The performance reports give the CPU cost of calling different procedure types and you can compare the cost of using these methods to other processing which you might do.
- There are no hard and fast rules about whether to call an external procedure or not. It will very much depend on what code you want to access. It is important to bear in mind the cost of making the call against the function that is being executed. Is it really worth it if the external procedure is only a few lines of code. It might easier to re-write the code and make it available locally within the message flow.
- Database stored procedures can be a useful technique for reducing the size of the result set that is returned to a message flow from a database query. Especially where the result set from an SQL statement might contain hundreds or thousands of rows otherwise. The stored procedure can perform an additional refinement of the results. The stored procedure is close to the data and using it to refine results is a more efficient way of reducing the volume of data. Otherwise data has to be returned to the message flow only to be potentially discarded immediately.

Consider the use of patterns

Patterns provide top-down, parameterized connectivity of common use cases

- e.g. Web Service façades, Message oriented processing, Queue to File...

They help describe best practice for efficient message flows

- There are also quick to create and less prone to errors

Write your own patterns too!

- Help new message flow developers come on board more quickly

The screenshot shows the IBM WebSphere Message Broker Toolkit interface. The main window displays the 'View Pattern Specification' for the 'Service Proxy: static endpoint pattern'. The left pane shows a tree view of patterns, including 'Application Integration', 'SAP', 'File Processing', 'Record Distribution', 'Matt Patterns', 'Message-based Integration', 'Service Enablement', 'Service Access', 'Service Facade', 'Service Virtualization', and 'Service Proxy'. The right pane contains the following text:

Service Proxy: static endpoint pattern

Use this pattern to provide decoupling between Web service requesters and Web service providers by virtual service that is bound directly to the target service provider.

Use this pattern:

- When you do not want the client to access the service directly, either because the address of the service is located might change, or because it must be hidden to control access to the service.
- To support service access over HTTP or HTTPS
- When you want to provide logging of all requests to the service provider, or when you want to provide error handling capabilities without making changes to the service provider

Solution

The solution is to implement a message flow that provides a proxy for the provider Web service and logging and error handling capabilities.

The diagram illustrates the message flow for the 'Service Proxy: static endpoint pattern'. It shows a 'Service Requester' sending a message to a 'Service Proxy: static endpoint' component. This component then sends the message to a 'Service Provider' component. A 'Set provider address' component is shown as part of the proxy, indicating that the proxy handles the address resolution and routing of the request to the provider.

Consider your operational environment

- Network topology
 - Distance between integration server and data
- What hardware do you need?
 - Including high availability and disaster recovery requirements
 - IBM can help you!
- Transactional behaviour
 - Early availability of messages vs. backout
 - Transactions necessitate log I/O – can change focus from CPU to I/O
 - Message batching (commit count)
- What are your performance requirements?
 - Now...

...and in five years

Consider how your integration logic will scale

- How many integration servers?
 - As processes, integration servers provide isolation
 - Higher memory requirement than threads
 - Rules of thumb:
 - Group small numbers of applications in an integration server
 - Allocate all instances needed for a message flow over those integration servers
 - Assign heavy resource users (memory) to specialist integration server
- How many message flow instances?
 - Message flow instances provide thread level separation
 - Lower memory requirement than integration servers
 - Potential to use shared variables
 - Rules of thumb:
 - There is no pre-set magic number
 - What message rate do you require?
 - Try scaling up the instances to see the effect; to scale effectively, message flows should be efficient, CPU bound, have minimal I/O and have no affinities or serialisation.

General notes (1 of 10)

- So far we have focused on the message and contents of the message flow. It is important to have an efficient message flow but this is not the whole story. It is also important to have an efficient environment for the message flow to run in.
- We collectively refer to this as the environment. It includes:
 - Configuration of the integration node and any servers
 - Configuration of the associated queue manager
 - The topology of the environment in which the messages are processed
 - Business database configuration
 - Hardware
 - Software
- It is important that each of these components is well configured and tuned. When this occurs we can get the best possible message throughput for the resources which have been allocated.
- We will now briefly look at each of these aspects. The aim is to outline those aspects which you should be aware of and further investigate rather than to provide full guidance in this presentation.

General notes (2 of 10)

- It is possible to run an integration node as a trusted application on Windows, Solaris, HP-UX and AIX. The benefit of running in trusted mode is that the cost of an application communicating with the queue manager is reduced and MQ operations are processed more efficiently. It is thus possible to achieve a higher level of messaging with a trusted application. However when running in trusted mode it is possible for a poorly written application to crash and potentially corrupt the queue manager. The likelihood of this happening will depend on user code, such as a plugin node, running in the message flow and the extent to which it has been fully tested. Some users are happy to accept the risk in return for the performance benefits. Others are not.
- It is possible to increase the number of instances of a message flow which are running. Similarly you can increase the number of integration servers and assign message flows to those integration servers. This gives the potential to increase message throughput as there are more copies of the message flow. There is no hard and fast rule as to how many copies of a message flow to run. For guidelines look at the details in the Additional Information section
- Tuning is available for non MQ transports. For example:
 - When using HTTP you can tune the number of threads in the HTTP listener
 - When using JMS nodes follow the tuning advice for the JMS provider that you are connecting to.
- As the integration node is dependent on the queue manager to get and put MQ messages the performance of this component is an important component of overall performance.
- When using persistent messages it is important to ensure the queue manager log is efficient. Review log buffer settings and the speed of the device on which the queue manager log is located.
- It is possible to run the WebSphere queue manager channels and listener as trusted applications. This can help reduce CPU consumption and so allow greater throughput.
- In practice an integration node's queue manager is likely to be connected to other queue managers. It is important to examine the configuration of these other queue managers as well in order to ensure that they are well tuned.

Complete your session evaluations online at www.SHARE.org/Orlando-Eval

General notes (3 of 10)

- The input messages for a message flow do not magically appear on the input queue and disappear once they have been written to the output queue by the message flow. The messages must somehow be transported to the input queue and moved away from the output queue to a consuming application.
- Let us look at the processing involved to process a message in a message flow passing between two applications with different queue manager configurations.
 - Where the communicating applications are local to the integration server, and they use the same queue manager, processing is optimized. Messages do not have to move over a queue manager to queue manager channel. When messages are non-persistent no commit processing is required. When messages are persistent 3 commits are required in order to pass one message between the two applications. This involves a single queue manager.
 - When the communicating applications are remote from the integration node's queue manager, messages passed between the applications must now travel over two queue manager to queue manager channels (one on the outward, another on the return). When messages are non-persistent no commit processing is required. When messages are persistent 7 commits are required in order to pass one message between the two applications. This involves two queue managers.
- If the number of queue managers between the applications and the integration node were to increase, so would the number of commits required to process a message. Processing would also become dependent on a greater number of queue managers.
- Where possible keep the applications as close as possible in order to reduce the overall overhead.
- Where multiple queue managers are involved in the processing of messages it is important to make sure that all are optimally configured and tuned.

General notes (4 of 10)

- The extent to which business data is used will be entirely dependent on the business requirements of the message flow. With simple routing flows it is unlikely that there will be any database access. With complex transformations there might be involved database processing. This could involve a mixture of read, update, insert and delete activity.
- It is important to ensure that the database manager is well tuned. Knowing the type of activity which is being issued against a database can help when tuning the database manager as you can focus tuning on the particular type of activity which is used.
- Where there is update, insert or delete activity the performance of the database log will be a factor in overall performance. Where there is a large amount of read activity it is important to review buffer allocations and the use of table indices for example.
- It might be appropriate to review the design of the database tables which are accessed from within a message flow. It may be possible to combine tables and so reduce the number of reads which are made for example. All the normal database design rules should be considered.
- Where a message flow only reads data from a table, consider using a read only view of that table. This reduces the amount of locking within the database manager and reduces the processing cost of the read.

General notes (5 of 10)

- Allocating the correct resources to the integration node is a very important implementation step.
- Starve a CPU bound message flow of CPU and you simply will not get the throughput. Similarly neglect I/O configuration and processing could be significantly delayed by logging activities for example.
- It is important to understand the needs of the message flows which you have created. Determine whether they are CPU bound or I/O bound.
- Knowing whether a message flow is CPU bound or I/O bound is key to knowing how to increase message throughput. It is no good adding processors to a system which is I/O bound. It is not going to increase message throughput. Using disks which are much faster such as a solid state disk or SAN with a fast-write non-volatile cache will have a beneficial effect though.
- As we saw at the beginning IBM Integration Bus has the potential to use multiple processors by running multiple message flows as well as multiple copies of those message flows. By understanding the characteristics of the message flow it is possible to make the best of that potential.
- In many message flows parsing and manipulation of messages is common. This is CPU intensive activity. As such message throughput is sensitive to processor speed. Integration nodes will benefit from the use of faster processors. As a general rule it would be better to allocate fewer faster processors than many slower processors.
- We have talked about ensuring that the integration node and its associated components are well tuned and it is important to emphasize this. The default settings are not optimized for any particular configuration. They are designed to allow the product to function not to perform to its peak.
- It is important to ensure that software levels are as current as possible. The latest levels of software such as IBM Integration Bus and WebSphere MQ offer the best levels of performance.

General notes (6 of 10)

- Avoid use of array subscripts [] on the right hand side of expressions – use reference variables instead. See below. Note also the use of LASTMOVE function to control loop execution.

```
DECLARE myref REFERENCE TO OutputRoot.XMLNSC.Invoice.Purchases.Item[1];  
-- Continue processing for each item in the array  
WHILE LASTMOVE(myref)=TRUE DO  
-- Add 1 to each item in the array  
SET myref = myref + 1;  
-- Move the dynamic reference to the next item in the array  
MOVE myref NEXTSIBLING;  
END WHILE;
```

- Use reference variables rather than long correlation names such as InputRoot.DFDL.A.B.C.D.E. Find a part of the correlation name that is used frequently so that you get maximum reuse in the ESQL. You may end up using multiple different reference variables throughout the ESQL. You do not want to reference variable pointing to InputRoot for example. It needs to be deeper than that.

```
DECLARE myref REFERENCE TO InputRoot.DFDL.A.B.C;  
SET VALUE = myRef.D.E;
```

- Avoid use of EVAL if possible, it is very expensive!
- Avoid use of CARDINALITY in a loop, e.g.

```
while (I < CARDINALITY (InputRoot.DFDL.A.B.C[]))
```

This can be a problem with large arrays where the cost of evaluating CARDINALITY is expensive and as the array is large we also iterate around the loop more often. See use of reference variables and LASTMOVE above.

General notes (7 of 10)

- Combine ESQL into the minimum number of compute nodes possible. Fewer compute nodes means less tree copying.
- Use FORMAT clause (in CAST function) where possible to perform data and time formatting.
- Limit use of shared variables to a small number of entries (tens of entries) when using an array of ROW variables or order in probability of usage (current implementation is not indexed so performance can degrade with higher numbers of entries).
- For efficient code re-use consider using ESQL modules and schema rather than subflows. What often happens with subflows is that people add extra compute nodes to perform initialisation and finalisation for the processing that is done in the subflow. The extra compute nodes result in extra message tree copying which is relatively expensive as it is a copy of a structured object.
- Avoid use of PASSTHRU with a CALL statement to invoke a stored procedure. Use the "CREATE PROCEDURE ... EXTERNAL ..." and "CALL ..." commands instead
- If you do have to use PASSTHRU use host variables (parameter markers) when using the statement. This allows the dynamic SQL statement to be reused within DB2 [assuming statement caching is active]

General notes (8 of 10)

- Declare and Initialize ESQL variables in same statement

- Example:

```
Declare InMessageFmt      CHAR;  
Set InMessageFmt         = 'SWIFT';  
DECLARE C INTEGER;  
Set C = CARDINALITY(InputRoot.*[]);
```

- Better to use:

```
Declare InMessageFmt      CHAR 'SWIFT';  
DECLARE C INTEGER CARDINALITY(InputRoot.*[])
```

- Initialize MRM output message fields using MRM null/default rather than ESQL

- Messageset.mset > CWF>Policy for missing elements

- Use null value

- Cobol import

- Create null values for all fields if initial values not set in Cobol

- Avoids statements like

```
Set OutputRoot.MRM.THUVTILL.IDTRANSIN.NRTRANS      = '';
```

- For frequently used complex structures consider pre-building and storing in a ROW variable which is also a SHARED variable (and so accessible by multiple copies of the message flow). The pre-built structure can be copied across during the processing of each message so saving processing time in creating the structure from scratch each time. For an example of ROW and SHARED variable use see the message flow Routing_using_memory_cache which is part of the Message Routing sample in the IBM Integration Bus samples gallery.

General notes (9 of 10)

- For Java follow applicable points from ESQL like reducing the number of compute nodes
- Store intermediate references when building / navigating trees

Instead of

```
MbMessage newEnv = new MbMessage(env);
newEnv.getRootElement().createElementAsFirstChild(MbElement.TYPE_NAME, "Destination", null);
newEnv.getRootElement().getFirstChild().createElementAsFirstChild(MbElement.TYPE_NAME,
    "MQDestinationList", null);
newEnv.getRootElement().getFirstChild().getFirstChild()
createElementAsFirstChild(MbElement.TYPE_NAME, "DestinationData", null);
```

Store references as follows:

```
MbMessage newEnv = new MbMessage(env);
MbElement destination = newEnv.getRootElement().createElementAsFirstChild(MbElement.TYPE_NAME,
    "Destination", null);
MbElement mqDestinationList = destination.createElementAsFirstChild(MbElement.TYPE_NAME,
    "MQDestinationList", null);
mqDestinationList.createElementAsFirstChild(MbElement.TYPE_NAME, "DestinationData", null);
```

General notes (10 of 10)

- Although XPath is a powerful statement from a development point of view it can have an unforeseen performance impact in that it will force a full parse of the input message. By default it will retrieve all instances of the search argument. If you know there is only one element or you only want the first then there is an optimization to allow this to happen. The benefit of using this is that it can save a lot of additional, unnecessary parsing.
- The XPath evaluation in IBM Integration Bus is written specifically for the product and has a couple of performance optimizations that are worth noting.
- XPath performance tips:
 - Use /aaa[1] if you just want the first one
 - It will stop searching when it finds it
 - Avoid descendant-or-self (//) if possible
 - It traverses (and parses) the whole message
 - Use /descendant::aaa[1] instead of (//aaa)[1]

Server / flow instances

How many Integration Servers should I have?
How many Additional Instances should I add?

Integration Servers

- Results in a new process/address-space
- Increased memory requirement
- Multiple threads including management
- Operational simplicity
- Gives process level separation
- Scales across multiple servers

Additional Instances

- Results in more processing threads
- Low(er) memory requirement
- Thread level separation
- Can share data between threads
- Scales across multiple servers

Recommended Usage

- Check resource constraints on system
 - How much memory available?
 - How many CPUs?
- Start low (1 server, No additional instances)
- Group applications in a single integration server
- Assign heavy resource users to their own integration server
- Increment integration servers and additional instances one at a time
 - Keep checking memory and CPU on machine
- Don't assume configuration will work the same on different machines
 - Different memory and number of CPUs

Notes for slide 70 (1 of 4)

- Within an integration node it is possible to have one or more integration servers.
- Integration server is a container in which one or more message flows can run.
- The implementation of an integration server varies with platform. On Windows and UNIX platforms it is implemented as an operating system process. On z/OS it is implemented as an address space.
- The integration server provides separation at the operating system level. If you have message flows which you must separate for some reason, you can achieve this by assigning them to different integration servers.
- An individual message flow runs as an operating system thread on the Windows and UNIX platforms and as a Task Control Block (TCB) on z/OS.
- It is possible to run more than one copy of a message flow in an integration server, in which case there will be multiple threads or TCBs running the same message flow. Equally you can run a message flow in more than one integration server. In which case there will be one or more threads or TCBs running the message flow in each of the processes or address spaces to which the message flow has been assigned.
- A significant benefit of using IBM Integration Bus is that the threading model is provided as standard. The message flow developer does not usually need to explicitly provide code in order to cope with the fact that multiple copies of the message flow might be run.
- How many copies and where they are run is an operational issue and not a development one. This provides significant flexibility.
- The ability to use multiple threads or TCBs and also to replicate this over multiple processes or address spaces means that there is excellent potential to use and exploit multiprocessor machines.

- In testing and production you will need to decide which message flows are assigned to which integration servers and how many integration servers are allocated. There are a number of possible approaches: Allocate all of the message flows in to one or two integration servers: Have an integration server for each message flow; Split message flows by project and so on. Before considering what the best approach is, lets look at some of the characteristics of integration servers and additional instances.
- Integration server:
 - Each integration server is an operating system process or address space in which one or more message flows run. Each new integration server will result in an additional process or address space being run.
 - An integration server might typically require ~150MB of memory to start and load executables. Its size after initialisation will then depend on the requirements of the message flows which run within it. Each additional integration server which is allocated will need a minimum of another ~150MB so you can see that using a high number of integration servers is likely to use a large amount of memory quickly.
 - As well as the threads needed to run a message flow, an integration server also has a number of additional threads which are used to perform management functions. So allocating many integration servers will result in more management threads being allocated overall.
 - An integration server provides process level separation between different applications. This can be useful for separating applications.

Notes for slide 70 (3 of 4)

- A common allocation pattern is to have one or possibly two integration servers per project and to then assign all of the message flows for that project to those integration servers. By using two integration servers you build in some additional availability should one execution fail. Where you have message flows which require large amounts of memory in order to execute, perhaps because the input messages are very large or have many elements to them, then you are recommended to keep all instances of those message flows to a small number of integration servers rather than allocate over a large number of integration servers [It is not uncommon for an integration server to use 1GB+ of memory.]. Otherwise every integration server could require a large amount of memory as soon as one of the large messages was processed by a flow in that integration server. Total memory usage would rise significantly in this case and could be many gigabytes.
- As with most things this is about achieving a balance between the flexibility you need against the level of resources (and so cost) which have to be assigned to achieve the required processing

- Additional Instance:
 - Each new additional instance results in one more thread being allocated in an existing integration server. As such the overhead is low. There will be some additional memory requirements but this will be significantly less than the ~150MB that is typically needed to accommodate a new integration server.
 - Message flows running as instances in a single integration server can access common variables called shared variables. This gives a cheap way to access low volumes of common data. The same is not true of messages flows assigned to different integration servers.
- When assigning message flows to integration servers there is no fixed algorithm imposed by IBM Integration Bus. There is significant flexibility in the way in which the assignment can be managed. Some users allocate high numbers of integration servers and assign a few message flows to each. We have seen several instance of 100+ integration servers being used. Others allocate many message flows to a small number of integration servers.
- A key factor in deciding how many integration servers to allocate is going to be how much free memory you have available on the machine.

Agenda

- What are the main performance costs inside message flows?

... and what are the best practices that will minimize these costs?

- What other performance considerations are there?
- Understanding your integration node's behavior

Some tools to understand your integration node's behaviour

- PerfHarness – Drive realistic loads through the runtime
 - <https://ibm.biz/JMSPerfHarness> and search for “PerfHarness”.
- OS Tools
 - Run your message flow under load and determine the limiting factor.
 - Is your message flow CPU, memory or I/O bound?
 - e.g. “perfmon” (Windows), “vmstat” or “top” (Linux/UNIX) or “SDSF” (z/OS).
 - This information will help you understand the likely impact of scaling (e.g. additional instances), faster storage and faster networks
- Third Party Tools
 - RFHUtil – useful for sending/receiving MQ messages and customising all headers
 - NetTool/Fiddler – useful for testing HTTP/SOAP
 - Process Explorer – Windows tool to show which files are in use by which processes
 - Java Health Center – to diagnose issues in Java nodes
- MQ / Integration Explorer
 - Queue Manager administration
 - Useful to monitor queue depths during tests
 - Resource Statistics, Activity Log
- IBM Integration Bus Web UI (V9 onwards)

Displaying broker at the process level on z/OS

- Use SDSF to display the Integration Server address space and find the CPU and memory usage.

```

SDSF PROCESS DISPLAY MVD1 ALL LINE 1-11 (11)

Reporting & Chargeback

- System Management Facilities (SMF)
 - IBM Integration Bus allows operational staff to control the gathering of SMF data on a per message flow basis. The message flow developer does not need to instrument their design in any way.
 - Enables efficient and effective tuning of message flows.
 - Allows infrastructure departments to charge users according to their utilization of integration node facilities.
- Coordinated Reporting
 - SMF also allows subsystems to report performance and accounting information at the same time for a given processing interval.
 - Makes it possible to correlate statistics between IBM Integration Bus, MQ and DB2 subsystems and artefacts.

The Do's and Don'ts of IBM Integration Bus Performance

8/11/2015

Accounting and Statistics Timers

- Information is gathered at regular intervals according to timers. There are two classes of timers, internal and external.
- Archive and Snapshot timers are internal timers set by integration node parameters which govern when these data are written to their destinations.
- An external timer is available on z/OS, namely ENF37. ENF is also important to allow consolidated reporting of SMF information across major subsystems, e.g. you might coordinate queue manager and integration node activity to best understand how to tune your queue manager for particular flows.

A Variety of Output Destinations and Formats

- It's possible to gather this information in different formats according to technology used to access it.
- On z/OS there is the option to generate SMF type 117 records, having subtypes 1 and 2 depending on the granularity of information requested by the user for a particular flow.
- There is also the option of generating Publish Subscribe (XML), UserTrace and JSON.
- You may request different output destinations for Snapshot and Archive Stats by Message Flow.

Options for Reporting Scope and Granularity

- z/OS SMF can be collected for any integration node within a SYSPLEX. It can be integrated with all other SMF enabled z/OS products and subsystems - literally hundreds!
- UserTrace is collected for the integration node. This data is human readable and relatively useful if you're prototyping.
- PubSub can be collected for any integration node throughout the domain. This is incredibly powerful; it means you can sit anywhere in a domain and request information about particular nodes in a flow on a particular integration server on a integration node on a different machine! OR you could put in wild card subscriptions to gather information from several different sources!
XML is very structured, which makes it ideal for multi platform reporting.

View accounting & statistics using the WebUI

- Control statistics at all levels
- Easily view and compare flows, helping to understand which are processing the most messages or have the highest elapsed time
- Easily view and compare nodes, helping to understand which have the highest CPU or elapsed times.
- View all statistics metrics available for each flow

SMF Record Structure

BipSmf.h

Notes on slide 81

SMF 117 records describe the A&S information

- The subtype of SMF 117 records written depends on the data currently being collected.
- A type 1 record is produced when a flow is only collecting message flow or threads data. A single type 1 record is produced with all threads included.
- Type 2 records are produced when a flow is collecting node data. When only node data is collected, a single type 2 record is written to SMF, whereas when data for nodes and terminals are being collected, multiple type 2 records are written to SMF.

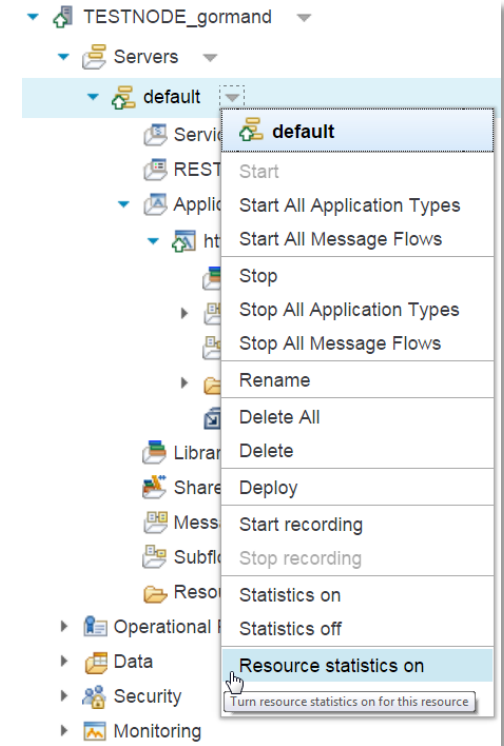

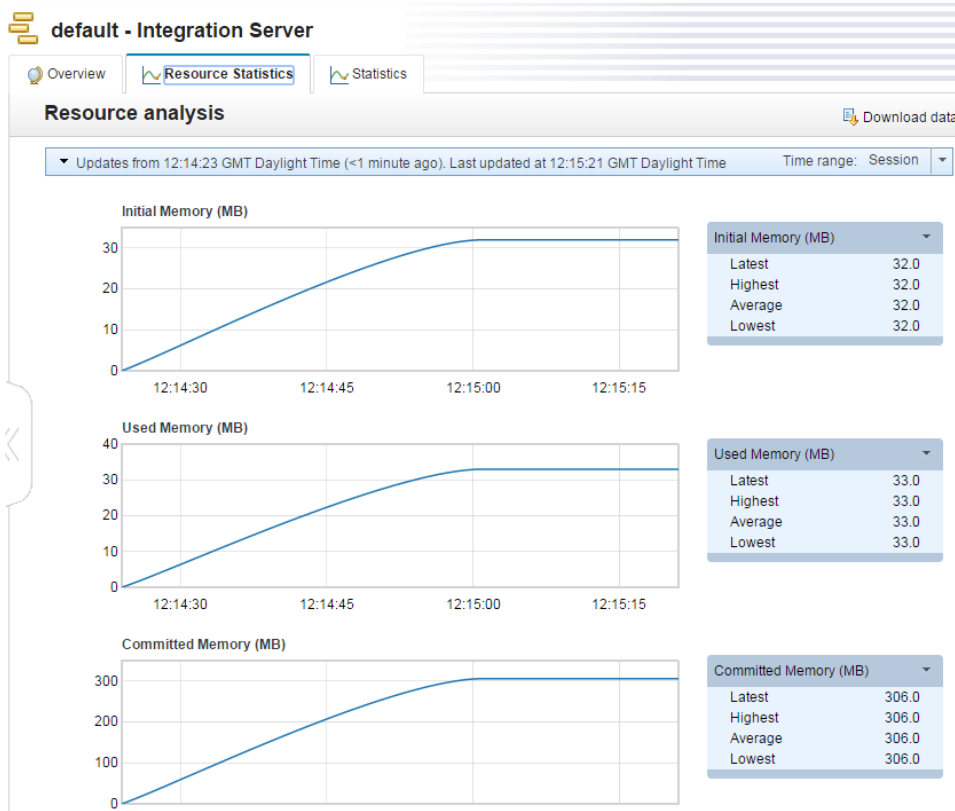

BipSMF.h describes the SMF records

- You can use the BipSMF.h header file to produce your own reports.

The integration node / server userid must be permitted to the BPX.SMF facility class profile to write SMF records.

Integration node resource statistics

- The IBM Integration Bus WebUI (V10) enables you to start/stop resource statistics on the integration server, and view the output.

Workload Management

Workload Scaling

- z/OS SYSPLEX brings a huge amount of potential processing capacity to the IBM Integration Bus with up to 141 z13 processors.
- Message flows have a built-in multiprocessing capability. Each *instance* of a message flow can execute on a separate thread (z/OS TCB) allowing the integration server to easily exploit multiple CPUs

Workload Isolation

- Simply assign separate integration server address spaces to different types of work.

z/OS Individual Integration Server Workload Management

- Integration Servers automatically assigned to `JOBACCT` token
- Use WLM Classification panels to map `JOBACCT` to Service and Report classes

MP	JOBNAME	StepName	ProcStep	JobID	Owner	SrvClass	RptClass	SysName	C	Pos	DP	Real	Paging	SIO	CPU%	ASID	ASIDX	EX
	MQ05BRK	LNEXPERT	BROKER	STC63060	MQ05BRK	STCFAST	COLIN	MVD1		IN	F4	55,031	0.00	3.62	0.03	205	00CD	
	MQ05BRK	MQ05BRK	BROKER	STC63059	MQ05BRK	STCUSER	MQ05	MVD1		IN	EC	30,901	0.00	0.00	0.05	208	00D0	
	MQ05BRK	DAVE	BROKER	STC63061	MQ05BRK	STCUSER	DQ05BASE	MVD1		IN	EC	56,046	0.00	3.62	0.03	240	00F0	

- Goal Oriented Resource Allocation (WLM)
 - When an IBM Integration Bus integration server address space starts, it is assigned a JOBACCT token. This can then be classified in Workload Manager (WLM) to service and report classes. This enables systems programmers to assign different goals (typically response time) to this service class through WLM configuration choices
 - The ability to assign WLM service classes to message processing workload has two significant benefits
 - As work passes through subsystems which are WLM enabled, the service class can be maintained. Resources such as CPU and IO “follow” users’ work requests to make sure these requests meet, if possible, the goals set by WLM
 - WLM classification means that in the event of resource constraint (at peak time for example), high priority workloads can receive appropriate resource to ensure that critical workloads are completed at the expense of less important work

- Workload Scaling
 - z/OS SYSPLEX brings a huge amount of potential processing capacity to IBM Integration Bus.
 - IBM Integration Bus is designed to exploit all of these capabilities without users having to explicitly design their message flows differently .
 - Message flows have a built-in multiprocessing capability.
 - Each instance of a message flow can execute on a separate thread (z/OS TCB) allowing the integration server to easily exploit multiple CPUs.
 - If a flow is not able to process enough messages due to CPU constraint, it is a simple step to assign more instances to the message flow to dynamically increase the number of eligible CPUs for processing. This does not involve flow design or outage .
 - And as we've seen, it's simple to scale message flows across the SYSPLEX by deploying to multiple integration servers within the SYSPLEX domain. Again, this reconfiguration process is dynamic and does not require restart .
- Workload Isolation
 - From a storage isolation perspective, integration servers are completely separated, storage in one address space is not visible to another. Moreover, if the event of a failure, an integration server is restarted without affecting any other integration servers owned by the integration node; failures are isolated to integration servers.

Testing and Optimising Message Flows

- Run driver application (e.g. *PerfHarness*) on a machine separate to the Integration Bus server for load testing
- Test flows in isolation
- Use real data where possible
- Avoid pre-loading queues
- Use a controlled environment – access, code, software, hardware
- Take a baseline before any changes are made
- Make ONE change at a time.
- Where possible retest after each change to measure impact
- Start with a single flow instance/server and then increase to measure scaling and processing characteristics of your flows

Performance Reports

- IIB V9 reports
 - IIB V9 Performance Reports - <https://ibm.biz/IIBv9Perf>
 - IIB V9 Performance Samples - <https://ibm.biz/IIBv9PerfSamples>
- Previous reports
 - <http://www-1.ibm.com/support/docview.wss?uid=swg27007150>
- Consists of 2 Sections:
 - High level release highlights and use case throughput numbers
 - Detailed low level metrics (nodes/parsers)
- Please send us your feedback!

Performance improvements in IIB V10 over IIB V9

- The IBM Integration Bus V10 runtime performance exceeds that of V9 in a number of key areas including:
 - DFDL scenarios show a ~20% reduction in cost per message
 - Graphical Data Mapper when accessing a Database show a ~10% reduction in cost per message
 - JSON parser shows an ~18% reduction in cost per message
 - HTTP Nodes and SOAP nodes over HTTP show a ~5% reduction in cost per message
 - SOAP over JMS using MQ show a ~10% reduction in cost per message
 - FTE nodes show an ~18% reduction in cost per message
 - Reduction in cost of ~50% when declaring statics in an ESQL compute node
- Administration response times have been improved by as much as 33% for functions such as connect and deploy, and 23% for start and stop.
- Out-of-the-box defaults have been improved for SOAP, HTTP and TCP/IP ensuring that TCPNoDelay and connection persistence options are set optimally.
- Reduced memory in the Integration Server runtime for some key customer scenarios, by the implementation of shared libraries (as opposed to libraries in v8/v9 which were static), ESQL static improvements, and changes to the internal data structures for flows and subflows.

Integration Bus V9: Performance highlights

- IBM Integration Bus V9 performance exceeds that of WebSphere Message Broker 8001 by more than 20% when using the DFDL parser for data parsing and serialisation, and the Graphical Data Mapper for message transformation.
- The performance of processing messages over HTTP and TCP/IP has also been improved, with similar performance gains.
- A new WebUI statistics view enables runtime performance to be analysed and monitored.

Summary
